INTRODUCTION

Grasslands of the Rocky Flats alluvial surface have attracted interest for some time because of their distinctive plant species composition that includes big bluestem and little bluestem, both grasses with their central distribution in the eastern Great Plains and both requiring greater moisture than is typically present in the western Great Plains. Branson et al. (1965) studied these areas along with grasslands growing on different soils nearby and documented the basic nature and distinction of these grasslands. They pointed out the paradox of coincidental occurrence of mountain and plains species on the grasslands occupying the surface of the Rocky Flats alluvium and speculated on the reasons that these species requiring more moisture than climate would normally provide would occur here. The nature of this ecosystem has also been acknowledged by the U.S. Soil Conservation Service (now Natural Resources Conservation Service) in the description for Cobbly Foothill range site (December 1975) in which co-dominance of big bluestem, little bluestem, and mountain muhly is acknowledged. Also set forth in the range site description is the dependence of the type on the occurrence of soils in which 1) high rock volume reduces the volume of effective soil and magnifies incident moisture and 2) argillic B horizons (heavy-textured subsoils) accompany high moisture-holding capacities. Similar observations were made previously by Branson et al.

The Rocky Flats alluvial surface has been the subject of geomorphic/quaternary stratigraphic studies for some time also. Many researchers have examined the age of the surface and its relationship to other terraces along the east slope of the Front Range. In one of the most recent studies, Birkeland et al. (1996) placed the age at something older than 1.69 to 1.82 million years, making it one of the oldest, if not the oldest geological surface in Colorado.

In late October 1994, at the request of Western Aggregates, seeking to permit gravel mining on the site, ESCO Associates undertook an examination of a grassland area in W2 Sec. 16, R70W, T2S. Purposes of this examination were 1) to begin to assess the extent and distinguishing characteristics of the grassland, 2) to document through limited quantitative sampling the species composition/density in the proposed Phase 2 mining area in W2 Sec. 16, and the upper portions of the Woman Creek drainage, and 3) to set forth the critical features of a reclamation plan for the Sec. 16 grassland were it to be mined and reclaimed. Comparison of the Section 16

Phase 2 proposed mining area and the Woman Creek drainage was undertaken to provide some technical basis for discussion of the degree to which conservation of the Woman Creek drainage would protect plant community characteristics that may be deemed important in the Section 16 Phase 2 mining area, especially warm season grass abundance and overall species composition and richness.

Results of these 1994 studies were reported in detail in ESCO (1994). Although this grassland had been referred to as Xeric Tallgrass Prairie (CNHP 1993), it will be referred to simply as Bluestem Grassland here to avoid presupposition that this ecosystem is necessarily like or unlike any other that exists and may have been categorized previously.

Since that time, interest has continued in the degree to which this grassland ecosystem in general, and its representation in the school section (Section 16), constitutes a valuable resource that should be perpetuated even to the exclusion of development of other resources that may be represented on the site such as gravel resources, commercial/industrial development , or other uses.

In 1996, ESCO Associates undertook the data collection portion of a study of these grasslands as they occur in Section 16 on Rocky Flats, in adjacent areas of the Rocky Flats surface, and elsewhere in northern Jefferson County and adjacent Boulder County. This study was part of a joint effort between Jefferson County Open Space Department, Jefferson County Nature Association, the Jefferson County Soil Conservation District, the Colorado State Land Board, and Western Aggregates, which mines gravel on Rocky Flats in the area where these grasslands occur. Data have been collected from a total of 33 sample sites in both 1996 and 1997.

METHODS

Quantitative data from the sample sites were collected in August 1996 as well as in April/May, June, and August/September 1997. Quantitative sampling has taken two forms, cover sampling and frequency/presence sampling. Cover sampling has provided reliable estimates of the abundance of the more common and extensive species at each of the sites, while frequency data have provided a look at the less common as well as the dominant species.

Sample Location

Samples were located subjectively with consideration of incorporating the variability of each site. A few samples thought to be clearly different were included to provide a context for the other sites. Sample locations are shown on Maps 1 through 3. At each location, the end points of the sample transect were marked with a rebar stake driven flush with the ground (for subsequent use with a metal detector), a fiberglass or steel post, and a cairn of rocks. Jefferson County Open Space personnel surveyed these endpoints with Global Positioning System (GPS) equipment to establish permanent record of them.

Cover

The point intercept method of cover assessment was chosen because it provides superior objectivity and repeatability; the inherent tendency to collect the most information on the more abundant species has been countered through use of a total vascular species inventory along the sample transect (see below). In addition, frequency plot data have been collected in one late summer and one spring sampling to provide further details of the abundance of less common species.

Point intercept cover sampling was developed early in the history of plant ecology (Levy and Madden 1933), and translated into varying forms by subsequent researchers (Goodall 1952, Winkworth and Goodall 1962).

Cover data were tabulated as interceptions of a point with plant species, soil, standing dead plant material (produced in a previous year), litter (fallen dead plant material), or rock. Plant material produced during the sample year and still standing was tallied by species. The point was optically projected using a Cover-Point Model 5 Optical Point Projector. The sample was taken at a randomly located and randomly oriented 50 m transect. Permanent marking of the endpoints was accomplished as described above.

Frequency

Frequency data were collected in August 1996 and April/May 1997. These data were taken in each of ten plots located at 5m intervals along each 50m transect. At the suggestion of the technical committee overseeing the study, data were separately collected and tabulated from 20cm x 50cm plots and 100cmx100cm plots. In each plot, all species present were tallied. For each species, the number of plots in which the plant was observed was divided by the number of plots observed (10). Thus, for example, if Species A occurred in seven plots, its frequency for the transect is 7/10, or 70 percent.

Species Presence

In June 1997, in order to assess the presence of any species that had not been apparent in May 1997 sampling, sample transects were revisited in June 1997. At this time, all species present within one meter to either side were tallied. This provided a means of expeditiously monitoring species composition without the lengthy frequency plot process.

RESULTS

Cover data from August 1996 are present in Table 96-1, and those from August 1997 are presented in Table 97-1. Frequency data from August 1996 and May 1997 are not included here because of their great volume and are available upon request. Species presence data from June 1997 are likewise available upon request.

Big bluestem is a species with presettlement distribution centered in areas with annual precipitation of greater than about 30 inches. Its presence has attracted attention to grassland ecosystems in the piedmont of the Front Range of Colorado because the average annual precipitation in this area is only about 13 to 18 inches and moisture-loving species such as big bluestem are not common. In addition, native grasslands of any sort in our area are rare now that residential and commercial development by humans has extended across our landscapes so far and fast.

Because it is a key primary species of interest, most of the sampled grassland ecosystems have a strong presence of big bluestem (Andropogon gerardii) which varied in 1997 from 0 to 35 percent cover and averaged 9.1 percent cover over all samples. However, the distinguishing composition of the Rocky Flats Bluestem Grassland is the simultaneous presence of big bluestem and mountain muhly (Muhlenbergia montana). The latter varied in 1997 from 0 to 18 percent cover and averaged 4.1 percent over all samples. Little bluestem (Schizachyrium scoparium) is often present and in some years visually very conspicuous, but its presence is intermittent. It averaged 1.2 percent cover in August 1997 sampling. Besides the graminoid dominants, the extensive presence of the endemic Porter's aster(Aster porteri) seems to distinguish these environments and may suggest some important things about the nature and significance of the ecosystems.

Review of the data from all sampled sites reveals that the ecosystems present on the Rocky Flats alluvial surface on the Flatirons series soils that are referred to here as Rocky Flats Bluestem Grassland are characterized by the dominance of big bluestem, mountain muhly, and Porter's aster. Samples 1, 2, 3, 4, 5, 10, 11, 15, 16, 17, 18, 19, 21, 22, 23, and CC-1, all sites on the main Rocky Flats surface on Flatirons series soils, averaged 8.0 percent cover by big bluestem, 7.8 percent cover by mountain muhly, 1.9 percent cover by little bluestem, and 6.3 percent cover by Porter's aster. Cover by these same species in all other samples averaged 10.2, 0.6, 0.5 and 0.8 percents, respectively. Thus, big bluestem was actually more abundant in the non-typical areas than in the main area of what is being referred to here as Rocky Flats Bluestem grassland. However, mountain muhly and Porter's aster are greatly more abundant in the Rocky Flats Bluestem grassland and little bluestem is slightly more abundant.

DISCUSSION

Abundant presence of big bluestem has been a guiding general concept in identifying areas for inclusion in the study. The co-dominance of mountain muhly is characteristic of the grassland ecosystems on Rocky Flats and in my opinion separates them from the other occurrences of big bluestem-dominated grasslands in Jefferson, Boulder and El Paso Counties along the Front Range of Colorado. By comparison, tallgrass occurrences in the City of Boulder Open Space tallgrass

natural areas are for the most part distinctly moister than the Rocky Flats sites and in any case do not include much if any representation of mountain muhly (see ESCO 1991, 1992, 1993, 1994, 1995, 1996). Data from the Rocky Flats Environmental Technology Site (PTI 1997) demonstrate that sites adjacent to those of the current study have shown the same species composition. Big bluestem is a component of a large number of Front Range foothill plant communities, where they have been, in recent years less heavily grazed and summer moisture has been abundant (see for example ESCO 1998). Data from the U.S. Air Force Academy (ESCO 1991) show one area (sample 006) with species composition similar to the Rocky Flats Bluestem Grassland. However, the presences of big bluestem and Porter's aster are somewhat weaker than is the case on Rocky Flats.

Of the sites examined during this study, it is apparent to me that of the some 25 to 50 species present, most are species with fairly wide ecological amplitudes whose presence is not particularly diagnostic of the ecological nature of this plant community. Since most of these areas have experienced grazing by domestic livestock over the past 130 years or longer, including periods of abusive grazing intensity, most of these ecosystems are in a state of recovery or disequilibrium that affects their species composition. This condition of modification has allowed various opportunistic species of wide ecological amplitude to occupy sites that they might not have in presettlement times, or has allowed them to exist in abundances that are much different than they typically presented in presettlement times. Examples of species that fall into this category may include many native annual and biennial forbs (along with most introduced annual and biennial forbs), prickly pear cactus, and most other cacti, and perennial forbs such as purple prairie clover, blanket flower, spotted gayfeather, and narrowleaf scurfpea.

The task at hand in evaluation of the significance of particular plant communities is to to conscientiously and truthfully determine whether a given plant community of apparently differing species composition and limited extent is a significant natural feature worthy of preservation, or whether it is a vestige of human land management and chanceas reflected in short term abundance of opportunistic species is of critical central importance.

In evaluation of the data to ascertain whether the Rocky Flats Bluestem grasslands are really

different from other bluestem-dominated grasslands, species that occur with great fidelity or in distinctly different abundance on only the RFB sites were sought. Conversely, species conspicuous by their absence on RFB sites only could contribute to interpretation of the community.

Of species observed during 1996 and 1997 sampling, none are rare. Species considered rare by CNHP that are known to occur in the general area include Aristida basiramea and Viola pedatifida, both of which were specifically sought and neither of which was found.

Fendler sandwort (Eremogone fendleri aka Arenaria fendleri) and James nailwort (Paronychia jamesii), while not rare, are strongly associated with the samples in which big bluestem, mountain muhly, and Porter's aster are dominant. These two species may be present in response to past grazing use (witness their absence in the long-ungrazed sample CC-1 and their somewhat lower abundance in sample 15 through 19 in the recently ungrazed Rocky Flats Environmental Technology Site Buffer Zone). Similarly Solidago simplex (aka S. decumbens, S. spathulata) and S. nana, both mountain species, though not as commonly present as the sandwort and nailwort show a strong fidelity with the RFB sites. The frequency of occurrence of these species in the samples from this study is illustrated in Figure 1. These species are, I believe, useful in describing the distinctive features of the RFB and in understanding its basic ecology.

James nailwort is a species of the (dry) high plains (not the relatively moist tallgrass portion of the plains, however). In consideration of the presence of Fendler sandwort, Porter aster, and the goldenrods from moister environments, the occurrence of James nailwort in the most of the RFB samples is another example of the same paradox posed by the co-occurrence of big bluestem and mountain muhly.

Porter aster is an endemic species of the east slope mountains in Colorado. It has wide distribution in the foothills of Boulder and Jefferson Counties, but is usually present in small amounts. Its presence in the RFB grasslands in amounts of 4 to 8 percent absolute cover (9 to 18 percent of total vegetation cover) is substantially greater than its general occurrence. Note the relative vegetation cover of this and the other dominants in Figure 2. It should also be noted that it occurred abundantly in the ungrazed sample (CC-1) lest it be assumed that its

presence relates to grazing effects only.

If the Rocky Flats alluvial surface has been in place and has been essentially undisturbed for one and one-half to two million years across a great many shifts in climate over a period including most of the Pleistocene, in a geomorphic/geographic position that is naturally transitional, then the presence of evidence of diverse former plant communities from past ages and climates is not surprising. Maybe it is not surprising, but it does, I believe, point to a significance in its antiquity, historic, and educational value.

Given the various climatic changes of the Pleistocene that accompanied glacial formation and advance, there have likely been ample periods of cool, moist climate providing the opportunity for mountain species to be present on this site. The time in which the bluestems, nominally reflective of warm moist climate, may have been added to the site, whether earlier or later is not known and numbers among the important questions potentially to be answered during research by geologists and ecologists on this site in years to come.
